SUMMARY

The analysis of patient blood transcriptional profiles offers a means to investigate the immunological mechanisms relevant to human diseases on a genome-wide scale. In addition, such studies provide a basis for the discovery of clinically relevant biomarker signatures. We designed a strategy for microarray analysis that is based on the identification of transcriptional modules formed by genes coordinately expressed in multiple disease data sets. Mapping changes in gene expression at the module level generated disease-specific transcriptional fingerprints that provide a stable framework for the visualization and functional interpretation of microarray data. These transcriptional modules were used as a basis for the selection of biomarkers and the development of a multivariate transcriptional indicator of disease progression in patients with systemic lupus erythematosus. Thus, this work describes the implementation and application of a methodology designed to support systems-scale analysis of the human immune system in translational research settings.

INTRODUCTION

Patient-based microarray transcriptional studies aim to discover biomarkers and to identify novel biological knowledge that will unravel the mechanisms of disease pathogenesis. However, these goals are met with considerable challenges. The use of gene expression microarrays in clinical research has led to the establishment of biomarker signatures from the analysis of both tumor tissues (Alizadeh et al., 2000; Bittner et al., 2000; Golub

et al., 1999) and blood samples (Allantaz et al., 2007; Baechler et al., 2003; Bennett et al., 2003; Burczynski et al., 2005; Chaussabel et al., 2005; Cobb et al., 2005; Kaizer et al., 2007; Ramilo et al., 2007; Thach et al., 2005). Yet, questions have been raised regarding the value of this approach for the discovery of stable disease markers (Michiels et al., 2005). Among the concerns is the fact that results of microarray analyses are prone to include noise (i.e., false-positive results—see Ioannidis, 2005) and do not compare well between laboratories and/or platforms (Bammler et al., 2005; Hyatt et al., 2006; Irizarry et al., 2005; Jarvinen et al., 2004; Larkin et al., 2005; Shi et al., 2006).

Leveraging patient transcriptional profiles as a means to identify relevant immunological mechanisms is also proving to be a challenge. In fact, both microarray and patient-based studies are considered by immunologists as fundamentally descriptive: in the case of microarray studies, this is because the results of system-wide screens do not conform to the reductionist knowledge-discovery model prevailing in the field (Benoist et al., 2006); in the case of patient-based studies, it is because the means of testing hypotheses in order to prove a mechanism are de facto very limited (Steinman and Mellman, 2004). Yet, carrying out such studies in patients, at a systems level, is necessary to advance immunological knowledge accumulated from the study of model organisms (Benoist et al., 2006; Steinman and Mellman, 2004).

Indeed, as technology platforms for systems-wide analysis become more sophisticated and more accessible than ever before, it is essential to continue exploring novel strategies for the exploitation of large-scale data. Among those, approaches to uncover the modular organization and function of transcriptional systems have already shown promise (Mootha et al., 2003; Rhodes et al., 2005; Segal et al., 2004; reviewed in Segal et al., 2005). Indeed, such analyses can transform our perception of large-scale transcriptional studies beyond the level of individual genes or lists of genes.

The present work describes the implementation of a unique approach for the analysis of blood microarray transcriptional profiles, based on a modular data mining strategy. We showed that this approach could improve our understanding of disease pathogenesis and provide a basis for the selection of clinically relevant transcriptional biomarkers.

RESULTS

Construction of Peripheral-Blood Mononuclear Cell (PBMC) Transcriptional Modules

Comparing transcriptional profiles of two or more study groups generates long lists of differentially expressed genes. Because of the large number of comparisons performed (usually > 10,000), these results are permissive to noise, which in turn can affect biomarker discovery and data interpretation (Ioannidis, 2005; Michiels et al., 2005).

In order to circumvent these hurdles, we focused the analysis on small sets of coordinately expressed transcripts. Indeed, the probability for multiple transcripts to follow a complex pattern of expression across dozens or hundreds of conditions only by chance is low, and such sets of genes should therefore constitute coherent and biologically meaningful transcriptional units. Thus, we designed an algorithm for constructing sets of coordinately expressed transcripts (i.e., modules) from PBMC microarray profiles generated from a wide range of diseases. This stable modular framework was then used as a basis for the analysis of a separate PBMC data set.

The algorithm used for the construction of transcriptional modules is described in detail in the [Experimental Procedures](#) section (Figure S1, available online). In brief, the first step of the module-construction process analyzes expression patterns of transcripts across samples for individual diseases: sets of coordinately expressed transcripts were identified with an unsupervised clustering algorithm; in this case, the GeneSpring Version 7.1 (Agilent) implementation of the K-Means algorithm ($k = 30$). All transcripts detected in at least one sample were used as input; no screening for differential expression was performed. The second step of the module-construction process analyzed the “clustering behavior” of transcripts across diseases, taking into account the possibility that genes may cocluster in some diseases but not in others. Also, in our example, the transcripts that clustered together across all eight diseases were grouped to form a set of modules (round 1 of selection), and the stringency of the analysis was then decreased gradually to identify transcripts that belong to a similar K-means cluster in only a subset of diseases (round 2: seven out of eight diseases; round 3: six out of eight diseases). This analysis of gene-cluster membership across diseases relates to “graph theory,” which is used in the mathematics and computer-science fields to model pairwise relations between objects (Biggs, 1986). It is important to note that the module-selection process is “data-driven” and does not involve manual selection of genes by the investigator.

We implemented the module-construction strategy described above, using as input a total of 239 peripheral-blood mononuclear cell (PBMC) samples obtained from individuals with one of the following conditions: systemic juvenile idiopathic arthritis ($n = 47$), systemic lupus erythematosus ($n = 40$), type I diabetes

($n = 20$), metastatic melanoma ($n = 39$), acute infections (*Escherichia coli* [$n = 22$], *Staphylococcus aureus* [$n = 18$], Influenza A [$n = 16$]) or liver-transplant recipients undergoing immunosuppressive therapy ($n = 37$). Transcriptional profiles were generated with Affymetrix U133A and U133B GeneChips (> 44,000 probe sets). A total of 4742 transcripts, distributed among 28 sets, were selected after running of the module-construction algorithm described above (Figure S1; a complete list is provided in Table S1). Each module is assigned a unique identifier indicating the round and order of selection (i.e., M3.1 is the first module identified in the third round of selection).

The stringency of this algorithm was tested statistically by implementation of the same module-construction procedure after randomization of the original data set. This process was repeated 200 times, without a single module identified (See [Supplemental Experimental Procedures](#) for details). Therefore, the analysis of gene-cluster membership across multiple diseases provided a stringent means to identify PBMC transcriptional modules.

The next step consists of functional characterization of each module. Keyword occurrence in PubMed abstracts associated with the genes within each module were analyzed by literature profiling (Chaussabel and Sher, 2002). Differences in patterns of keyword occurrence across modules were observed as illustrated in Figure S2, and functional associations were identified for each of the 28 PBMC transcriptional modules (Table 1). Of 28 PBMC modules, 14 could be clearly linked with pathways or cell types involved in immune processes (as detailed below). Functional associations were also observed in the remaining 14 modules. M2.5, for example, includes genes encoding immune-related molecules—CD40, CD80, CXCL12, IFNA5, IL4R—as well as cytoskeleton-related molecules—Myosin, Dedicator of Cytokinesis, Syndecan 2, Plexin C1, Distrobrevin (see Table 1 for details). Thus, transcriptional modules form coherent transcriptional and functional units.

Using Modules to Map Transcriptional Changes in Health and Disease

After identifying sets of coordinately expressed PBMC transcripts on the basis of the analysis of patterns found in a wide range of diseases, we used this modular framework as a stable basis for analyzing individual PBMC data sets.

Modules were conceived as a stable framework for the analysis of data generated independently of the sets that were initially used for module construction. We analyzed PBMC microarray transcriptional profiles generated from 14 patients with acute *Streptococcus pneumoniae* infection and from ten age- and sex-matched healthy control subjects. This data set was not used in the module-selection process. Statistical comparisons between patient and healthy control groups were performed independently on a module-by-module basis (Mann-Whitney rank test, $p < 0.05$). The transcriptional profiles of differentially expressed genes were then represented on a graph for individual modules (Figure 1A). The pie chart indicates the proportion of differentially expressed transcripts for a given module (e.g., 49% of the 322 transcripts forming module M3.2 were overexpressed in patients with acute *S. pneumoniae* infection compared to healthy controls). As shown in Figure 1A, differentially expressed genes in each module were either predominantly overexpressed

Table 1. Functional Interpretation of Transcriptional Modules

Module I.D.	Number of Probe Sets	Keyword Selection	Interpretation
M 1.1	76	Ig, Immunoglobulin, Bone, Marrow, PreB, IgM, Mu.	<u>Plasma cells.</u> Includes genes coding for Immunoglobulin chains (e.g., IGHM, IGJ, IGLL1, IGKC, IGHD) and the plasma cell marker CD38.
M 1.2	130	Platelet, Adhesion, Aggregation, Endothelial, Vascular	<u>Platelets.</u> Includes genes coding for platelet glycoproteins (ITGA2B, ITGB3, GP6, GP1A/B) and platelet-derived immune mediators such as PPPB (pro-platelet basic protein) and PF4 (platelet factor 4).
M 1.3	80	Immunoreceptor, BCR, B cell, IgG	<u>B cells.</u> Includes genes coding for B cell surface markers (CD72, CD79A/B, CD19, CD22) and other B cell-associated molecules: early B cell factor (EBF), B cell linker (BLNK), and B lymphoid tyrosine kinase (BLK).
M 1.4	132	Replication, Repression, Repair, CREB, Lymphoid, TNF-alpha	<u>Undetermined.</u> This set includes genes encoding regulators and targets of the cAMP-signaling pathway (JUND, ATF4, CREM, PDE4, NR4A2, VIL2) and repressors of TNF-alpha mediated NF-KB activation (CYLD, ASK, TNFAIP3).
M 1.5	142	Monocytes, Dendritic, MHC, Costimulatory, TLR4, MYD88	<u>Myeloid lineage.</u> Includes genes encoding molecules expressed by cells of the myeloid lineage (CD86, CD163, FCGR2A), some of which are involved in pathogen recognition (CD14, TLR2, MYD88). This set also includes TNF-family members (TNFR2, BAFF).
M 1.6	141	Zinc, Finger, P53, RAS	<u>Undetermined.</u> This set includes genes coding for signaling molecules; e.g., the zinc-finger-containing inhibitor of activated STAT (PIAS1 and PIAS2) or the nuclear factor of activated T cells, NFATC3.
M 1.7	129	Ribosome, Translational, 40S, 60S, HLA	<u>MHC/Ribosomal proteins.</u> Almost exclusively formed by genes encoding MHC class I molecules (HLA-A,B,C,G,E)+ Beta 2-microglobulin (B2M) or ribosomal proteins (RPLs, RPSs).
M 1.8	154	Metabolism, Biosynthesis, Replication, Helicase	<u>Undetermined.</u> Includes genes encoding metabolic enzymes (GLS, NSF1, NAT1) and factors involved in DNA replication (PURA, TERF2, EIF2S1).
M 2.1	95	NK, Killer, Cytolytic, CD8, Cell-mediated, T cell, CTL, IFN-g	<u>Cytotoxic cells.</u> Includes genes encoding cytotoxic T cells and NK cell-surface markers (CD8A, CD2, CD160, NKG7, KLRs), cytolytic molecules (granzyme, perforin, granzulin), chemokines (CCL5, XCL1), and CTL/NK cell-associated molecules (CTSW).
M 2.2	49	Granulocytes, Neutrophils, Defense, Myeloid, Marrow	<u>Neutrophils.</u> This set includes genes encoding innate molecules that are found in neutrophil granules (lactotransferrin: LTF, defensin: DEAF1, bacterial permeability increasing protein: BPI, cathelicidin antimicrobial protein: CAMP...).
M 2.3	148	Erythrocytes, Red, Anemia, Globin, Hemoglobin	<u>Erythrocytes.</u> Includes hemoglobin genes (HGBs) and other erythrocyte-associated genes (erythrocytic alkaline: ANK1, glycophorin C: GYPC, hydroxymethylbilane synthase: HMBS, erythroid-associated factor: ERAF).
M 2.4	133	Ribonucleoprotein, 60S, Nucleolus, Assembly, Elongation	<u>Ribosomal proteins.</u> Includes genes encoding ribosomal proteins (RPLs, RPSs), Eukaryotic Translation Elongation Factor-family members (EEFs), and Nucleolar proteins (NPM1, NOAL2, NAP1L1).
M 2.5	315	Adenoma, Interstitial, Mesenchyme, Dendrite, Motor	<u>Undetermined.</u> This module includes genes encoding immune-related molecules (CD40, CD80, CXCL12, IFNA5, IL4R) as well as cytoskeleton-related molecules (Myosin, Dedicator of Cytokinesis, Syndecan 2, Plexin C1, Distrobrevin).
M 2.6	165	Granulocytes, Monocytes, Myeloid, ERK, Necrosis	<u>Myeloid lineage.</u> Includes genes expressed in myeloid-lineage cells (IGTB2/CD18, Lymphotoxin beta receptor, Myeloid related proteins 8/14 Formyl peptide receptor 1) such as Monocytes and Neutrophils.

Table 1. Continued

Module I.D.	Number of Probe Sets	Keyword Selection	Interpretation
M 2.7	71	No keywords extracted.	<u>Undetermined.</u> This module is largely composed of transcripts with no known function. Only 20 genes associated with literature, including a member of the chemokine-like factor superfamily (CKLFSF8).
M 2.8	141	Lymphoma, T cell, CD4, CD8, TCR, Thymus, Lymphoid, IL2	<u>T cells.</u> Includes genes encoding T cell surface markers (CD5, CD6, CD7, CD26, CD28, CD96) and molecules expressed by lymphoid lineage cells (lymphotoxin beta, IL2-inducible T cell kinase, TCF7, T cell differentiation protein mal, GATA3, STAT5B).
M 2.9	159	ERK, Transactivation, Cytoskeletal, MAPK, JNK	<u>Undetermined.</u> Includes genes encoding molecules that associate to the cytoskeleton (actin-related protein 2/3, MAPK1, MAP3K1, RAB5A). Also present are T cell-expressed genes (FAS, ITGA4/CD49D, ZNF1A1).
M 2.10	106	Myeloid, Macrophage, Dendritic, Inflammatory, Interleukin	<u>Undetermined.</u> Includes genes encoding for Immune-related cell surface molecules (CD36, CD86, LILRB), cytokines (IL15) and molecules involved in signaling pathways (FYB, TICAM2-Toll-like receptor pathway).
M 2.11	176	Replication, Repress, RAS, Autophosphorylation, Oncogenic	<u>Undetermined.</u> Includes kinases (UHMK1, CSNK1G1, CDK6, WNK1, TAOK1, CALM2, PRKCI, ITPKB, SRPK2, STK17B, DYRK2, PIK3R1, STK4, CLK4, PKN2) and RAS-family members (G3BP, RAB14, RASA2, RAP2A, KRAS).
M 3.1	122	ISRE, Influenza, Antiviral, IFN-gamma, IFN-alpha, Interferon	<u>Interferon-inducible.</u> This set includes interferon-inducible genes: antiviral molecules (OAS1/2/3/L, GBP1, G1P2, EIF2AK2/PKR, MX1, PML), chemokines (CXCL10/IP-10), signaling molecules (STAT1, STAT2, IRF7, ISGF3G).
M 3.2	322	TGF-beta, TNF, Inflammatory, Apoptotic, Lipopolysaccharide	<u>Inflammation I.</u> Includes genes encoding molecules involved in inflammatory processes (e.g., IL8, ICAM1, C5R1, CD44, PLAUR, IL1A, CXCL16) and regulators of apoptosis (MCL1, FOXO3A, RARA, BCL3/6/2A1, GADD45B).
M 3.3	276	Inflammatory, Defense, Lysosomal, Oxidative, LPS	<u>Inflammation II.</u> Includes genes encoding molecules inducing or inducible by inflammation (IL18, ALOX5, ANPEP, AOA, HMOX1, SERPINB1), as well as lysosomal enzymes (PPT1, CTSB/S, NEU1, ASAH1, LAMP2, CAST).
M 3.4	325	Ligase, Kinase, KIP1, Ubiquitin, Chaperone	<u>Undetermined.</u> Includes genes encoding protein phosphatases (PPP1R12A, PTPRC, PPP1CB, PPM1B) and phosphoinositide 3-kinase (PI3K) family members (PIK3CA, PIK32A, PIP5K3).
M 3.5	22	No keyword extracted	<u>Undetermined.</u> Composed of only a small number of transcripts. Includes hemoglobin genes (HBA1, HBA2, HBB).
M 3.6	288	Ribosomal, T cell, Beta-catenin	<u>Undetermined.</u> This set includes genes encoding mitochondrial ribosomal proteins (MRPLs, MRPs), mitochondrial elongation factors (GFM1/2), Sortin Nexins (SN1/6/14), as well as lysosomal ATPases (ATP6V1C/D).
M 3.7	301	Spliceosome, Methylation, Ubiquitin	<u>Undetermined.</u> Includes genes encoding proteasome subunits (PSMA2/5, PSMB5/8); ubiquitin protein ligases HIP2, STUB1, as well as components of ubiquitin ligase complexes (<i>SUGT1</i>).
M 3.8	284	CDC, TCR, CREB, Glycosylase	<u>Undetermined.</u> Includes genes encoding enzymes: aminomethyltransferase, arginyltransferase, asparagines synthetase, diacylglycerol kinase, inositol phosphatases, methyltransferases, helicases...
M 3.9	260	Chromatin, Checkpoint, Replication, Transactivation	<u>Undetermined.</u> Includes genes encoding kinases (IBTK, PRKRIR, PRKDC, PRKCI) and phosphatases (e.g., PTPLB, PPP2CB/3CB, PTPRC, MTM1, MTMR2).

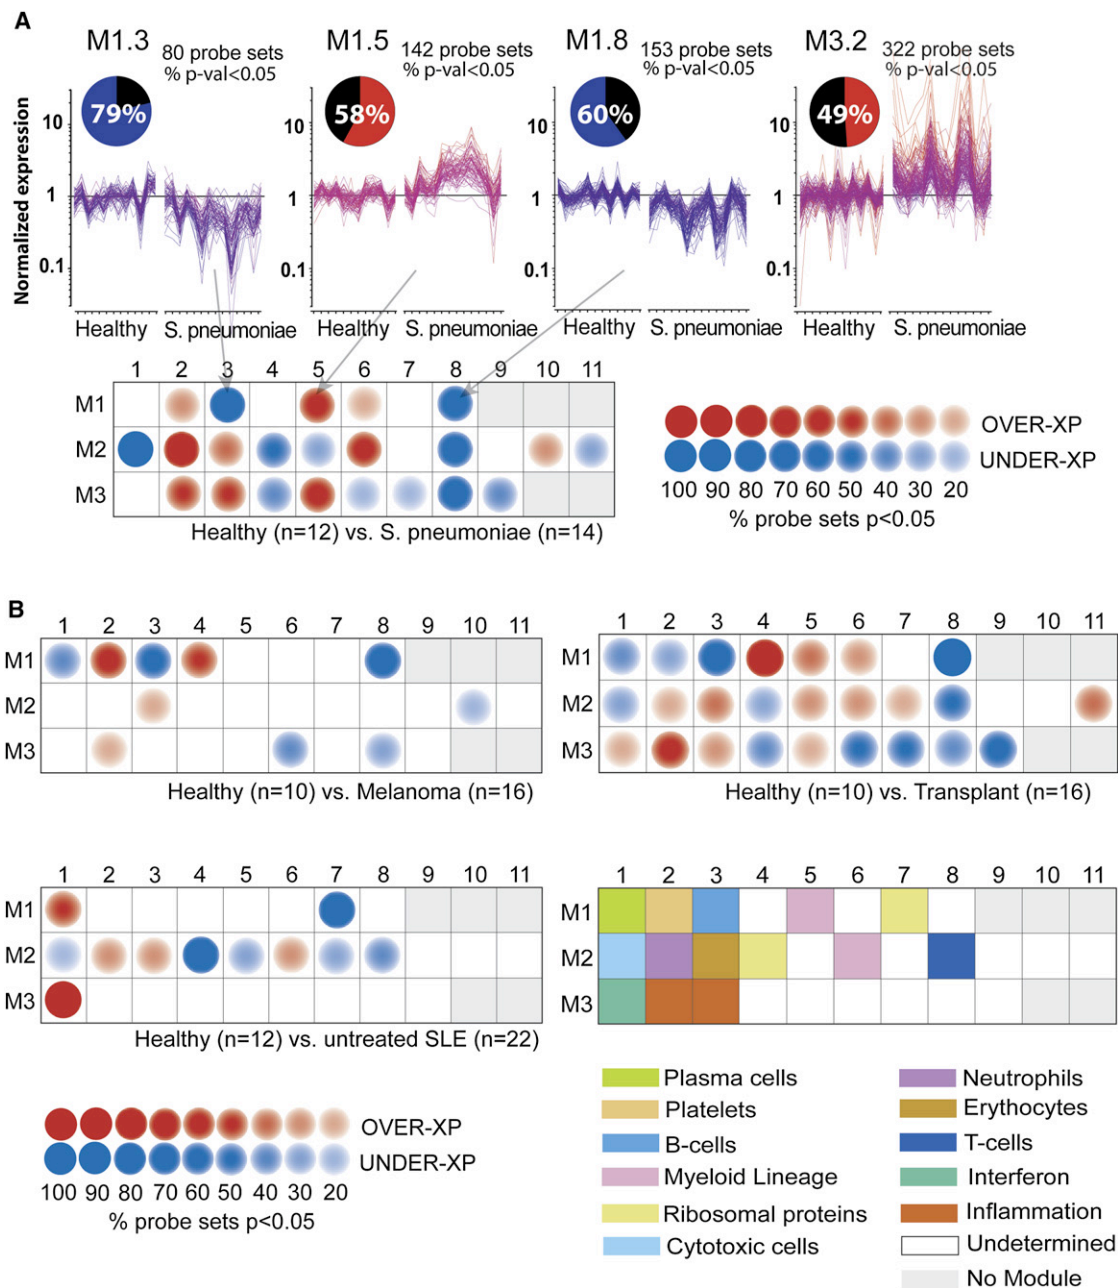

Figure 1. Analysis of Patient Blood Leukocyte Transcriptional Profiles

(A) Module-level analysis. Gene-expression levels from PBMCs of patients with acute *S. pneumoniae* infection and healthy volunteers were compared ($p < 0.05$, Mann-Whitney U test) in modules M1.3, M1.5, M1.8, and M3.2. Pie charts indicate the proportion of genes significantly changed for each module. Graphs represent transcriptional profiles of genes that were significantly changed. Each line shows levels of expression (y axis) of a single transcript across multiple conditions (samples, x axis). Expression is normalized to the median expression value of the control group. Results obtained for the 28 PBMC transcriptional modules are displayed on a grid. Coordinates indicate module IDs (e.g., M2.8 is row M2, column 8). Spots indicate the proportion of genes significantly changed for each module in patients with *S. pneumoniae* infection as compared to healthy controls. Red: overexpressed. Blue: underexpressed.

(B) Disease fingerprints. Three additional data sets were similarly processed. Profiles were obtained from patients with Systemic Lupus Erythematosus, liver-transplant recipients under pharmacological immunosuppression infection, and patients with metastatic melanoma. Functional interpretation is indicated on a grid by a color code. Detailed functional descriptions are provided in Table 1.

or predominantly underexpressed. This observation is notable because modules were not selected on the basis of differences in expression between study groups but, instead, on clustering patterns.

To graphically represent global transcriptional changes, spots were aligned on a grid, with each position corresponding to a different module (Figure 1A). Spot intensity positively correlates with the proportion of differentially expressed transcripts,

whereas spot color indicates the polarity of the change (red: overexpressed, blue: underexpressed). The resulting map represents molecular perturbations associated with a disease state. A blank grid would indicate that no significant differences exist between the disease and the healthy baseline. Conversely, the presence of blue and red spots as in Figure 1A indicates that expression levels of sets of transcripts are increased or decreased in patients with acute *S. pneumoniae* infection as compared to healthy controls. In addition, for the facilitation of data interpretation, modules' coordinates were associated to the functional categories that have been previously assigned (Figure 1B, Table 1). For instance, Modules M1.3 and M2.1, respectively, associated with B cells and cytotoxic cells and were underexpressed in the *S. aureus* group as compared to the healthy group, whereas modules M2.2 and M3.2, respectively, associated with neutrophils and inflammation and were overexpressed.

Thus, we showed that sets of transcriptional modules can be used as a reference for the analysis and interpretation of data generated independently from those used for module construction. Furthermore we have developed a means to visualize transcriptional changes on a module-by-module basis, which in conjunction with functional annotations yields an interpretable representation of microarray results.

We next generated module maps for three additional groups of patients (22 systemic lupus erythematosus patients [SLE], 16 metastatic melanoma patients, and 16 liver-transplant recipients), as well as their respective control groups, composed of 10 to 12 healthy donors who were matched for age and sex (Figure 1B, Table S2). Results for M1.1 and M1.2 alone distinguished all four diseases (*S. pneumoniae*: M1.1 = no change, M1.2 = overexpressed; SLE: M1.1 = overexpressed, M1.2 = no change; melanoma: M1.1 = underexpressed, M1.2 = overexpressed; transplant: M1.1 = underexpressed, M1.2 = underexpressed). A number of genes in M3.2 ("inflammation") were overexpressed in patients with melanoma or *S. pneumoniae* infection, as well as in transplant recipients, whereas genes in M3.1 ("interferon-inducible") were overexpressed in patients with SLE and, to a lesser extent, in transplant recipients. M2.1 and M2.8 include, respectively, cytotoxic cell-related genes and T cell transcripts, which are underexpressed in lymphopenic SLE patients and transplant recipients treated with immunosuppressive drugs. Overall, although these comparisons showed that modules can be shared between diseases (e.g., underexpression for M1.3 transcripts in both *S. pneumoniae* and melanoma groups), global modular changes remained disease-specific.

Module maps provide a means to organize and reduce the dimension of complex data and to thereby facilitate its interpretation. However useful it is, this oversimplified representation at the same time lacks the depth that systems-scale analyses are able to provide. Representing changes at the module level with a red or blue spot, for instance, does not indicate which of the genes are significantly changed. Indeed, a spot of the same color in two different diseases might be attributed to two different subsets of genes belonging to the same module. The disconnect between gene-level and module-level data is especially apparent when the results are presented in a static format; i.e., on paper. Thus, we have developed an interactive web interface allowing users to switch seamlessly between module-level data and gene-level data (Figure S3). Interactive module maps can be

accessed at www.biir.net/modules. In addition to the four data sets analyzed in the context of this manuscript, we loaded on this tool third-party data sets made publicly available by others (Burczynski et al., 2006). Mapping transcriptional changes in patients with Crohn's disease and ulcerative colitis highlighted similarity and differences between these diseases, with, for instance, a characteristic overexpression of transcripts linked to plasma cells (M1.1) in ulcerative colitis. This repository will be updated as more blood transcriptional data become available from our and other groups.

Using Modules as a Basis for the Discovery of Blood Transcriptional Biomarkers

Microarray gene-expression data generated from blood not only provide valuable insights into mechanisms of disease pathogenesis but also constitute a promising source of biomarkers. The difficulty, however, lies in the extraction of indicators of potential clinical value from the vast amounts of data generated. We used modular transcriptional data as the foundation of our biomarker-discovery strategy. This approach was implemented with the use of a data set generated from patients with SLE.

Microarray analyses have been carried out on PBMCs obtained from pediatric and adult SLE patients (Baechler et al., 2003; Bennett et al., 2003; Crow et al., 2003; Kirou et al., 2004). Using an earlier generation of Affymetrix arrays (~12,600 probe sets), we identified a type I interferon (IFN) signature in all pediatric patients with active diseases (Bennett et al., 2003). This analysis also revealed the presence of neutrophil, immunoglobulin (Ig), and lymphopenic signatures that correlated with the presence of low-density granulocytes, plasma cell precursors, and a reduction in lymphocyte numbers in SLE blood, respectively (Bennett et al., 2003).

These findings were confirmed in the present study, with significant changes observed in modules M3.1, M2.2, M1.1, and M2.8 (interferon-inducible, neutrophils, plasma cells, and T lymphocytes, respectively) for a new data set generated from a cohort of 22 pediatric lupus patients sampled at the time of diagnosis and before initiation of treatment, compared to healthy controls (Figure 1B). Transcriptional changes were observed in seven additional modules (M1.7, M2.1, M2.3, M2.4, M2.5, M2.6, and M2.7). Two of these modules, M1.7 and M2.4, included transcripts encoding ribosomal protein family members whose expression was recently found to be altered in acute infection and sepsis (Calvano et al., 2005; Thach et al., 2005). Furthermore, our unpublished observations have shown that in vitro exposure of purified human monocytes to interferon alpha results in a late downregulation of the transcripts forming these modules. In addition, marked changes in gene expression were also observed for modules M2.1 and M2.3, which include transcripts expressed in cytotoxic cells and in erythrocytes, respectively. Interestingly, the pattern of change in M2.1, M2.2, M2.3, and M2.4 within the SLE group was well-conserved across diseases. Indeed, increased expression for M2.2 and M2.3 and decreased expression for M2.1 and M2.4 were also observed in transplant recipients, as well as in patients with acute *S. pneumoniae* infections. This partial convergence is likely to reflect the existence of core transcriptional responses to disease or injury (e.g., inflammation).

The proposed biomarker-selection strategy relies on modules for reducing highly dimensional microarray data sets in a stepwise manner (Figure 2). Starting from the full set of 28 modules, only

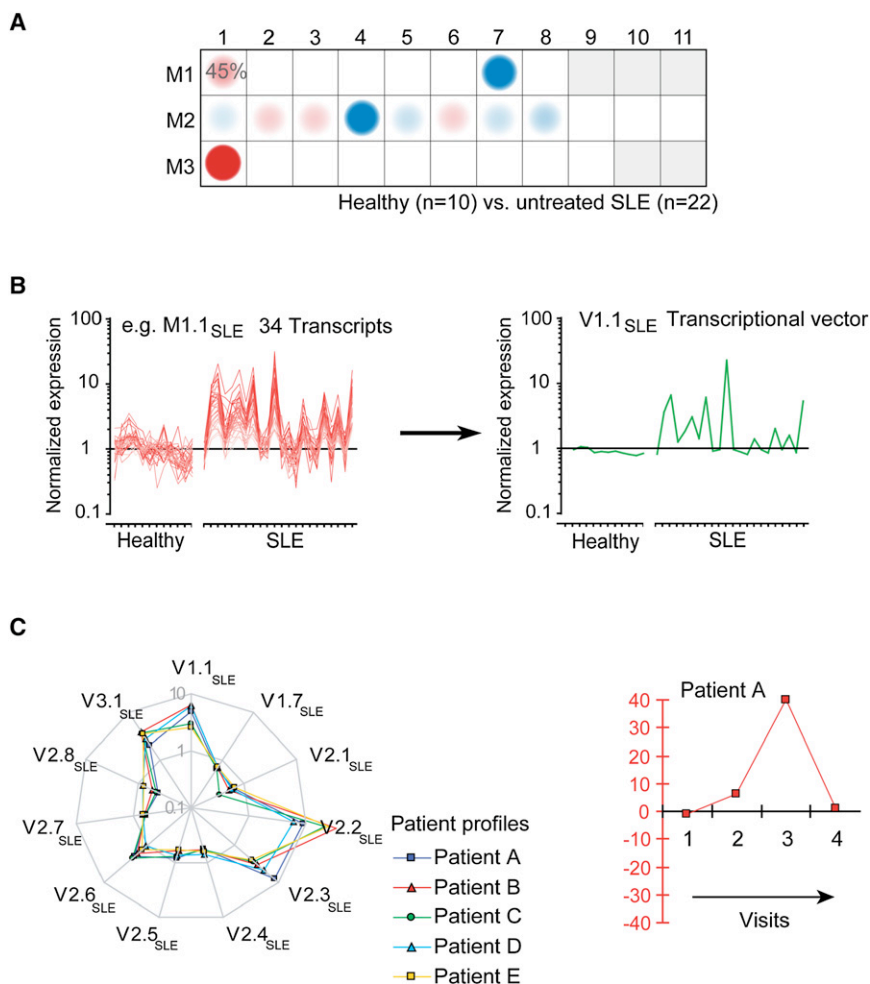

Figure 2. Module-Based Biomarker-Selection Strategy

Modules are used as a starting point for the generation of biomarker signatures and progressive reduction of the dimension of microarray data:

(A) Mapping global transcriptional changes with the use of a modular framework identified 11 modules for which at least 15% of the transcripts are significantly changed between controls and patients with SLE.

(B) Transcriptional vectors were generated by the averaging of the normalized expression values of differentially expressed transcripts for each one of the 11 modules selected.

(C) Composite expression values are plotted as vectors on a “spider graph.” Each line represents a patient profile. Multivariate scores can be generated to recapitulate the changes registered by several transcriptional vectors and monitor changes in an individual patient over time.

those for which a set minimum proportion of transcripts are significantly changed between the study groups are selected (Figure 2A; e.g., minimum proportion of differentially expressed transcripts at $p < 0.05 = 15\%$ overexpressed or underexpressed transcripts; in the example given, 11 SLE modules meet this criterion). This eliminates from the selection pool the modules registering fewer consistent changes that could be attributed to noise. The cutoffs used for gene selection can be adjusted to adapt the number of candidate markers that will be returned by this analysis.

We then generated composite values for each sample. The arithmetic average of normalized expression values across significantly overexpressed or underexpressed genes selected from each module was calculated (Figure 2B). Each resulting “transcriptional vector” recapitulates the expression of a given module (or a select set of genes within a module) in a given patient. A spider graph connects all the vector values obtained for each patient (Figure 2C). This is in contrast with the module maps defined earlier, which display the frequency of significant changes for an entire patient cohort module-by-module.

SLE Patient Profiles Are Linked to Disease Activity

Transcriptional vectors were derived for the entire cohort of 22 untreated pediatric SLE patients with the use of the set of 11

SLE modules detailed above (the 628 differentially expressed genes distributed among those 11 vectors are listed in Table S3). In Figure 3A, each line represents the expression profile of one patient; the thicker line shows the average expression for the patients forming this group. The values are normalized per gene with the use of the median expression value of healthy volunteers and are represented on a logarithmic scale. Figure 3B displays the expression pattern characteristic of healthy volunteers. Differences between the healthy group and the SLE group were statistically significant for each of

the modules ($p < 0.01$; Mann-Whitney U test). Patient profiles were also generated for an independent set of 31 children with SLE treated with steroids and/or cytotoxic drugs and/or hydroxychloroquine (Figure 3C, Table S4). Interestingly, average profiles for both treated and untreated patient cohorts were almost superimposable (Figure 3D—no significant difference at $p < 0.01$; V2.2 $p = 0.04$; Mann-Whitney U test). However, patient selection in both groups was such that they presented similar disease activity as measured by the clinical index SLEDAI (SLE disease-activity index: untreated patients average = 11.5 ± 7.9 , treated patients average = 9.4 ± 6.4 ; Student's t test $p = 0.3$).

In order to investigate a possible link between SLE activity and patient transcriptional profiles, we stratified samples solely on the basis of SLEDAI scores. Samples from patients with mild disease activity (SLEDAI [0–6]) presented a profile closer to that of healthy subjects (Figure 3E) whereas patients with high disease activity (SLEDAI [14–28]) presented an exacerbated profile (Figure 3F—comparison of mild versus high disease activity: V1.7, V2.2, V2.3, V2.4, V2.8, and V3.1: $p < 0.01$; V1.1 $p = 0.07$; V2.1 $p = 0.06$; V2.5 $p = .8$; V2.6 $p = 0.02$; V2.7 $p = 0.08$; Mann-Whitney U test).

These results suggest that composite transcriptional vectors identified in SLE patients are associated with disease severity and have potential value as biomarkers.

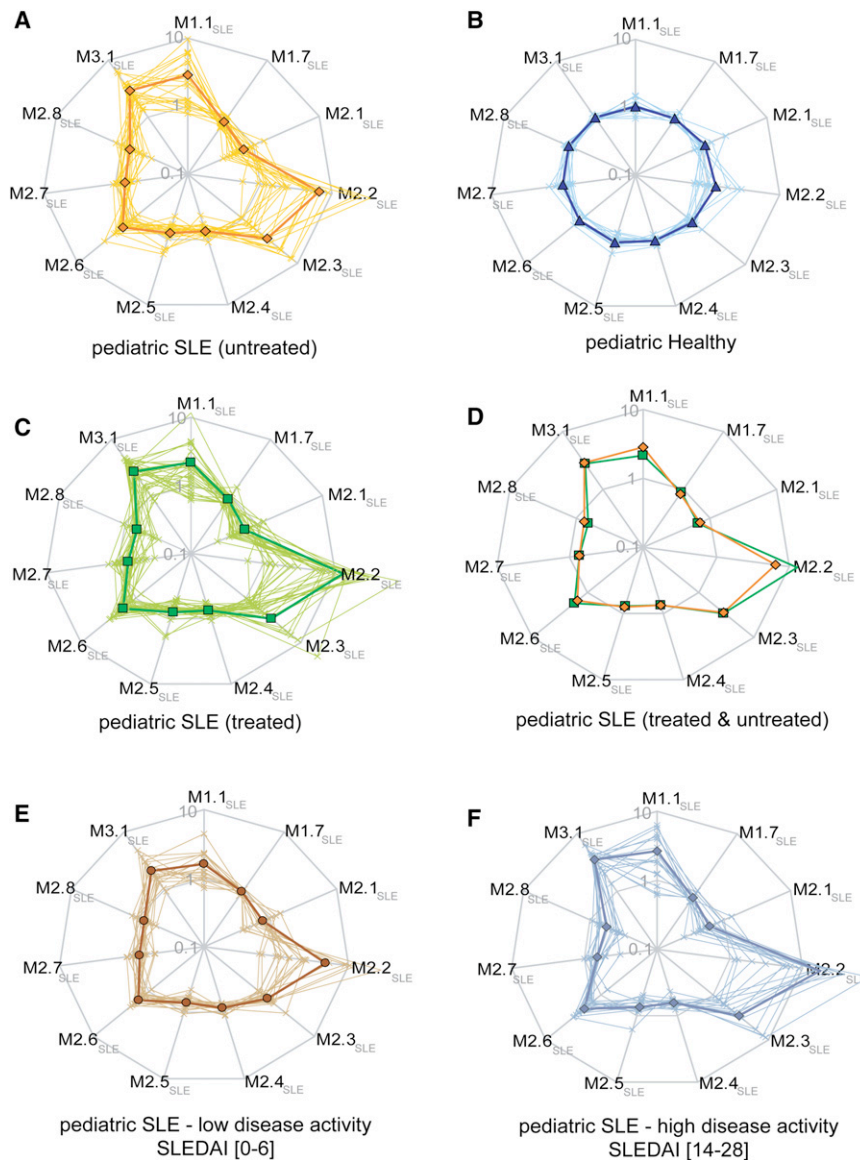

Figure 3. SLE Transcriptional Vectors

(A–C) Composite transcriptional vectors identified from a pediatric SLE patient population sampled prior to the initiation of therapy. Each line on the radar plot represents a patient profile (logarithmic scale). Values are normalized per gene with the use of the median expression value relating to healthy volunteers. The thicker line represents the average normalized expression profile for this group of patients (A). Profiles were generated for healthy volunteers (B) and an independent cohort of pediatric SLE patients under treatment (C). Green and orange colors indicate averaged normalized expression profiles for treated (green) and untreated (orange) SLE patient cohorts. (D) Patient profiles were plotted on the same vectors on the basis of clinical activity (SLEDAI), regardless of treatment. (E) Patients with low disease activity (SLEDAI scores from 0 to 6). (F) Patients with high disease activity (SLEDAI scores from 14 to 28).

whether such activity index could be generated from blood leukocyte microarray transcriptional data.

The analysis of pediatric SLE patient profiles carried out above showed a link between transcriptional vectors and clinical disease manifestations. We have previously found that expression of individual genes or gene signatures (such as interferon-inducible genes) could be affected by treatment (Bennett et al., 2003). Therefore, our aim was to maximize the number of transcriptional signatures used as a basis for the generation of a clinical indicator of disease activity. We computed correlations between composite expression values for individual dimensions (transcriptional vectors) and the clinical-activity index (SLEDAI)

Generating Multivariate Transcriptional Scores as Indicators of SLE Disease Progression

SLE is a multisystemic disease presenting a wide range of clinical and laboratorial abnormalities. Objectively assessing disease activity across patients or longitudinally in individual patients can therefore be challenging. At least six composite measures of SLE global disease activity have been developed (Bae et al., 2001; Bencivelli et al., 1992; Bombardier et al., 1992; Hay et al., 1993; Liang et al., 1989; Petri et al., 1999) and have been used to assess disease progression during clinical trials. These measures, however, rely on a series of clinical and laboratory findings and are cumbersome to obtain. The SLEDAI, one of the simplest measures, considers 24 different attributes that need to be obtained at every clinic visit. Additionally, given the heterogeneous nature of the clinical disease, not all SLE manifestations are computed within these measures, making the overall assessment of the patient sometimes difficult. Thus, establishment of an objective disease activity index would be beneficial. We assessed

for each of the patients in our untreated cohort (Figure 4A). We found that two dimensions (corresponding to V2.2 [“neutrophil”] and V3.1 [“interferon-inducible”] modules) correlated positively with disease activity, whereas dimensions corresponding to V1.7, V2.4, and V2.8 (‘‘ribosomal proteins’’ and ‘‘T cells’’) correlated negatively. We then verified that differences in expression observed for a selection of transcripts belonging to these five modules could be confirmed with real-time PCR. Two transcripts from M1.7, M2.2, M2.4, M2.8, and M3.1 were tested in ten healthy controls and 25 patients. Differences in expression were significant in nine out of the ten transcripts tested (*CCDC72*, *ELA2*, *MPO*, *FBL*, *EEF1D*, *IL23A*, *SIGLEC1* $p < 0.001$; *GATA3*, *MX1* $p < 0.05$; *GLTSCR2* $p = 0.8$). Only one of the transcripts tested, *GLTSCR2*, did not display the expected difference between control and SLE groups. This degree of concordance is consistent with rates reported in the literature (Bosotti et al., 2007). The discrepancy could be attributed to differences in probe selection for the respective assays.

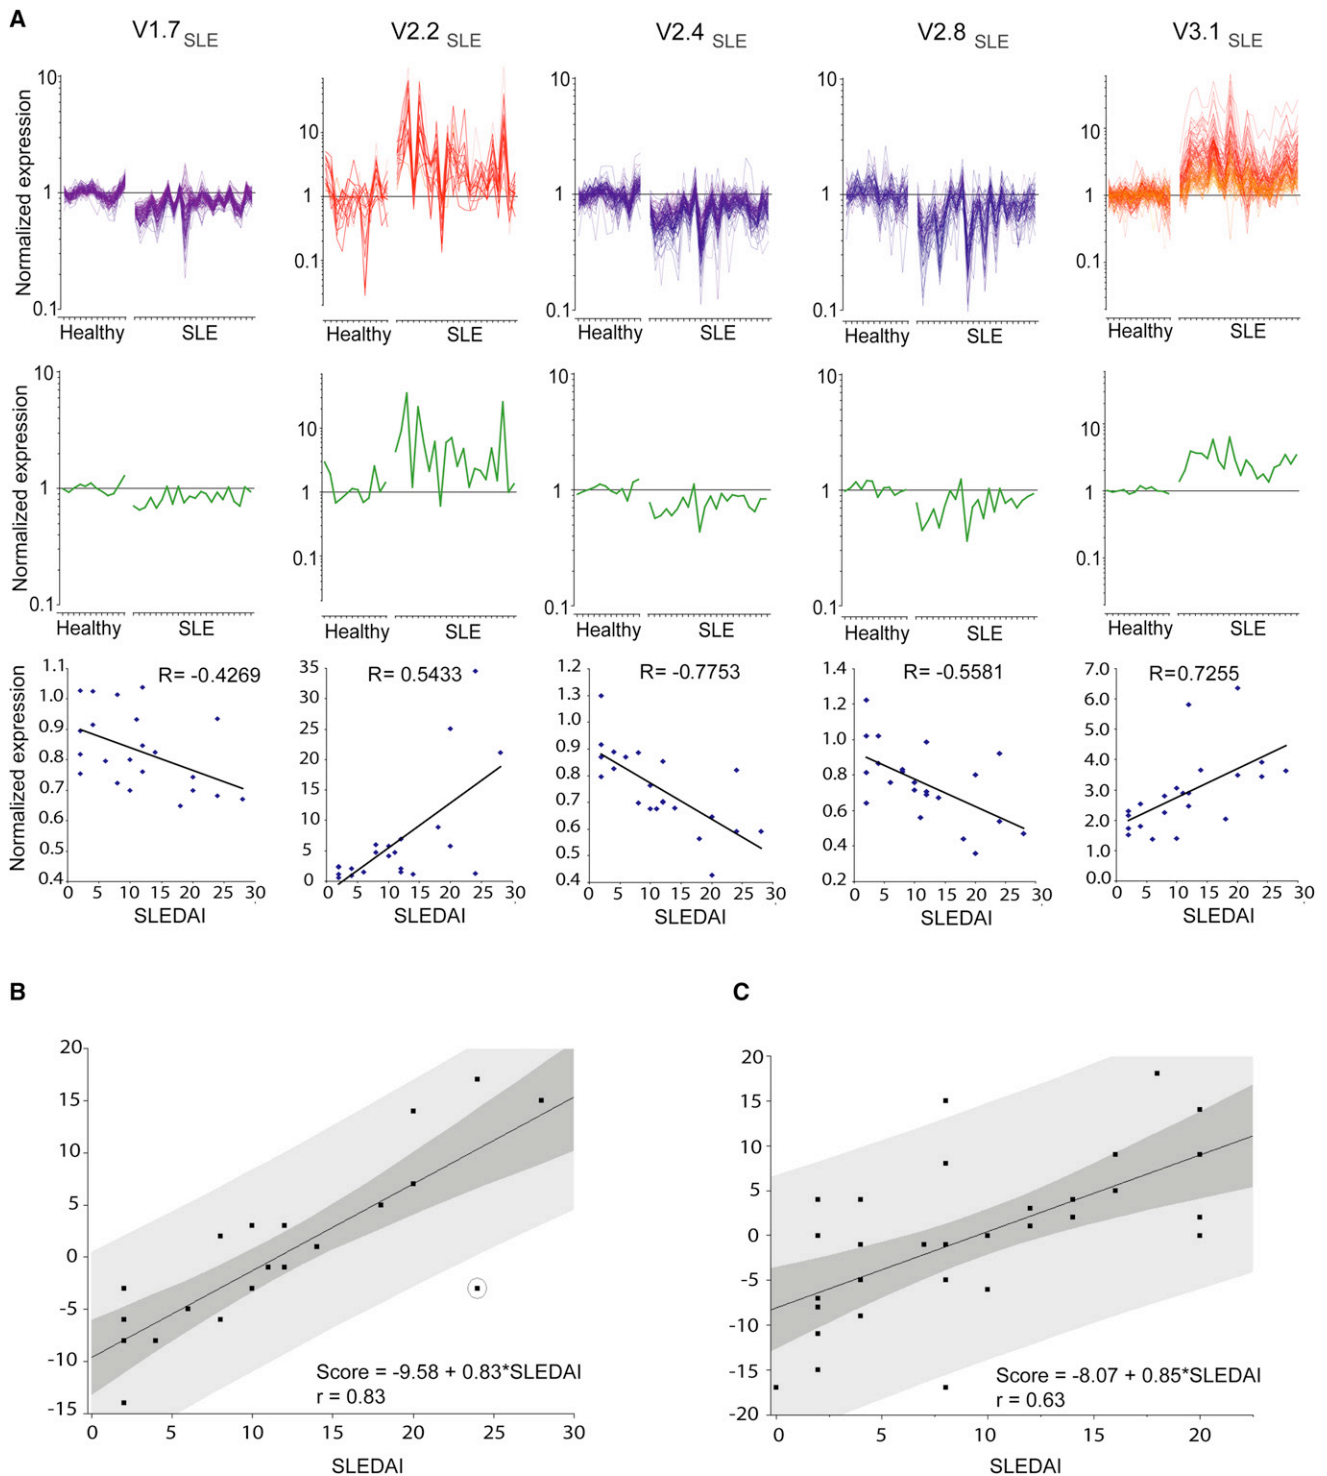

Figure 4. SLE Transcriptional Vectors Correlate with Disease Activity

(A) Expression profiles of genes forming vectors V1.7_{SLE}, V2.2_{SLE}, V2.4_{SLE}, V2.8_{SLE}, and V3.1_{SLE} correlating with a clinical SLE disease-activity index (SLEDAI). Graphs represent expression levels of individual transcripts forming each of the vectors in 12 healthy individuals and 22 untreated pediatric SLE patients. Average expression values across transcripts forming each vector are shown on the graph in yellow. Correlations between averaged vector expression values and SLEDAI scores are shown below (Spearman correlation).

(B) Multivariate scores were obtained for 22 untreated pediatric SLE patients by linear-regression analysis of multivariate transcriptional U scores (y axis) for vectors V1.7_{SLE}, V2.2_{SLE}, V2.4_{SLE}, V2.8_{SLE}, V3.1_{SLE}, and SLEDAI (x axis). The light shaded area indicates the 95% confidence limits for individual predicted values. The dark shaded area indicates the 95% confidence limits for the slope and intercept.

(C) The same analysis discussed in (B) was applied to 31 pediatric patients with SLE receiving different combinations of therapy.

Expression values obtained by real-time PCR for the nine differentially expressed transcripts were also significantly correlated with microarray data (Figures S4 and S5).

A nonparametric method for analyzing multivariate ordinal data was used to score the patients on the basis of these five dimensions (Spangler et al., 2004; Wittkowski et al., 2004). The advantage of this approach is that there is no need for additional assumptions and validations. Once the available knowledge is incorporated by the making of the initial transformations, the proposed scores are valid by construction, as long as each variable increases or decreases with the unobservable latent factor. Thus, no empirical evaluation is needed. Because no assumptions are made regarding the functional form of the relationship, U scores are scale-independent.

U-scores were obtained for all patients in the untreated cohort ($n = 22$). A polarity of 1 was attributed to vectors correlating positively with disease activity (i.e., Neutrophil: V2.2, Interferon: V3.1). The polarity of vectors correlating inversely with disease activity was set to -1 (T cells: V2.8 and Ribosomal proteins: V1.7 and V2.4). This allowed the ranking of all patients within this group. U scores have positive values (most-severe disease) or negative values (less-severe disease), reflecting the rank of each sample versus the other patients forming this cohort. The association between the multivariate “transcriptional scores” and SLEDAI was assessed with linear regression and was determined to be statistically significant (Figure 4B; $r = 0.83$, $df = 1$, $t = 6.66$, and $p < .0001$). The correlation achieved by this score was superior to its individual components. Using the same process, correlation between “transcriptional score” and SLEDAI was examined for the treated cohort of pediatric patients with SLE ($n = 31$) and was found to be statistically significant as well (Figure 4C; $r = 0.63$, $df = 1$, $t = 4.40$, $p = 0.0001$).

Thus, distinct immunological signatures associated with the pathogenesis of SLE have been reduced to a unique multivariate score correlating with disease activity.

Multivariate Transcriptional Scores are Used to Monitor Disease Progression in Patients with SLE

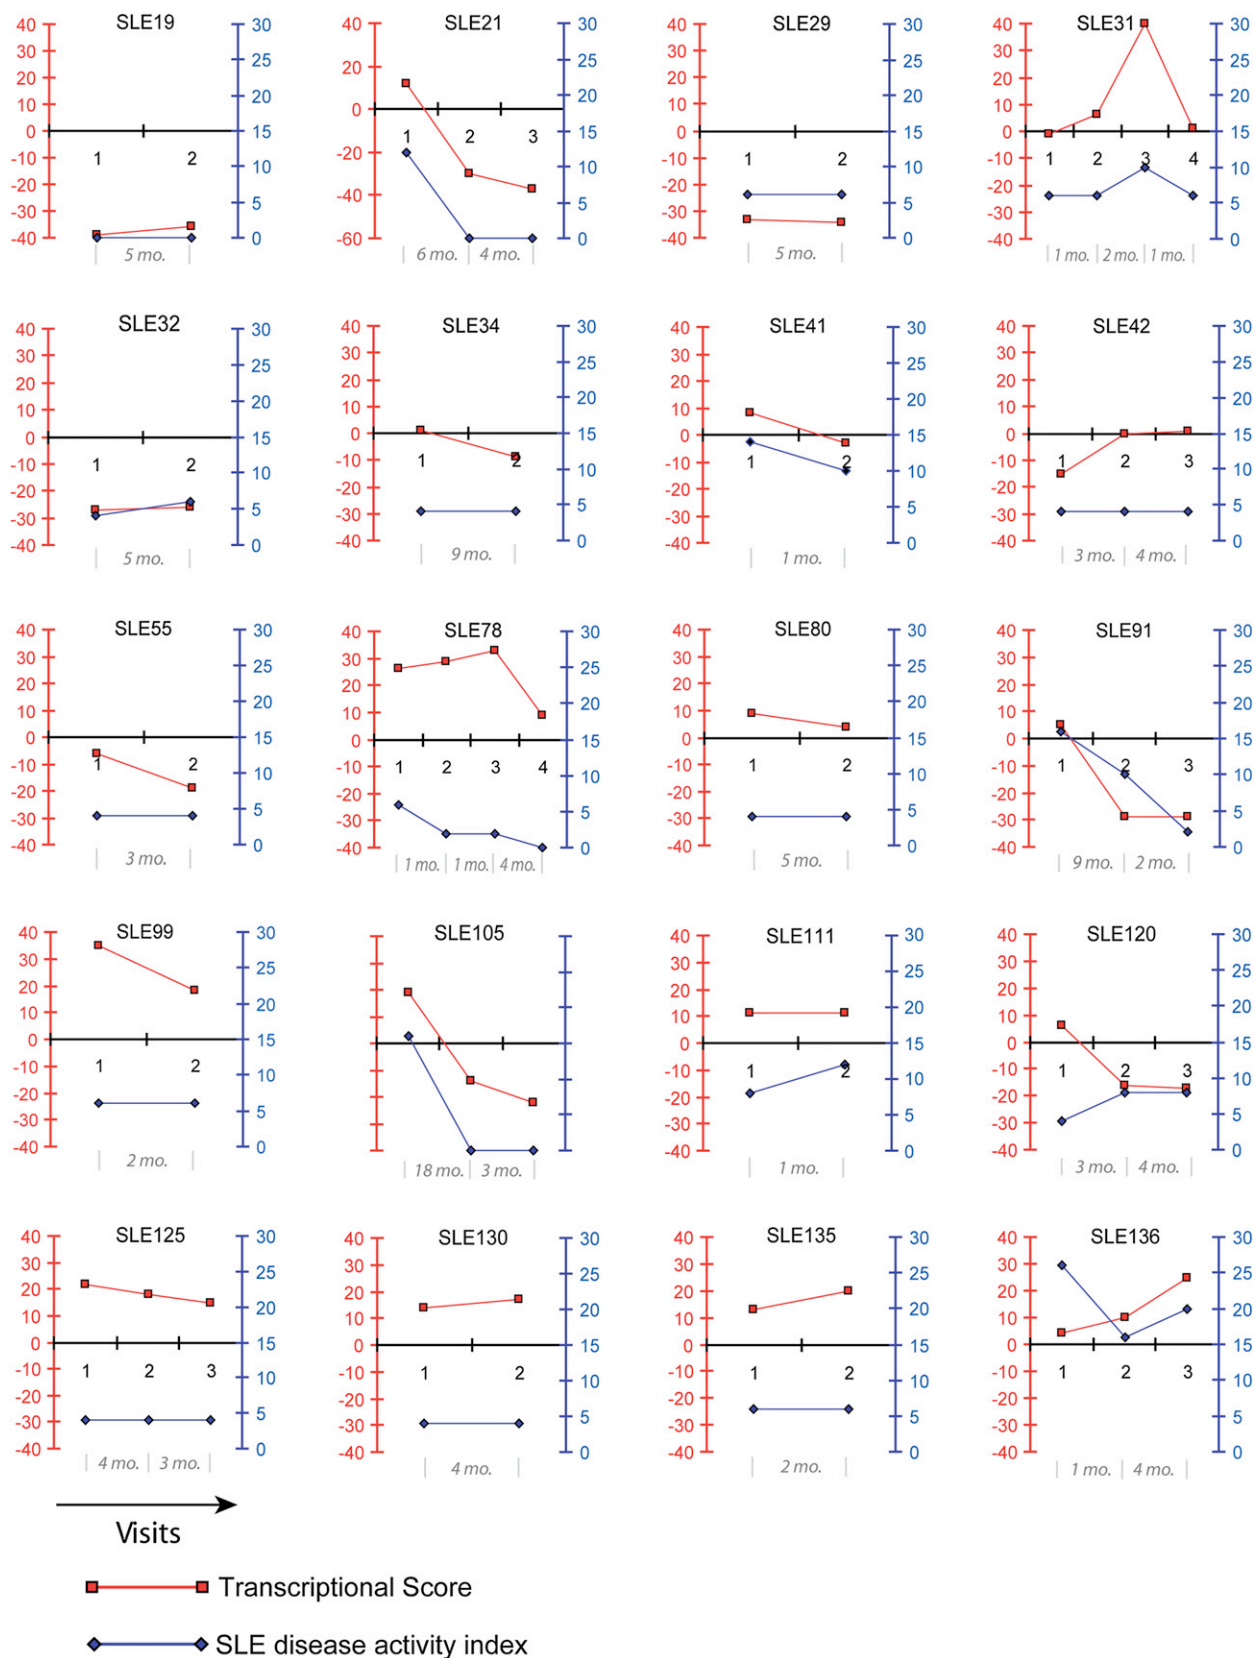

Lupus disease flares can lead to irreversible worsening of the patient's status. We tested the relevance of the multivariate transcriptional score for longitudinal monitoring of the disease activity in a cohort of 20 pediatric SLE patients (two to four time points/patient, intervals between each time point varied from one month to 18 months). Half of the patients had been included in our cross-sectional analysis before they were enrolled in this longitudinal study.

During the follow-up period, the SLEDAI fluctuated in ten patients and remained constant in the other ten (Figure 5). Parallel trends were observed between transcriptional U scores and SLEDAI longitudinal measures in a majority of patients. The positive association between SLEDAI and transcriptional scores was verified statistically with the use of a linear-regression model. The estimated model was: transcriptional score = $18.13 + 1.26$ (SLEDAI) $- 0.03$ (Days). The overall model was statistically significant ($df = 1$, $\chi^2 = 28.44$, $p < .0001$), as was the association between the SLEDAI scores and the transcriptional scores ($df = 28$, $t = 2.41$, $p = 0.0229$). For every one-unit increase in SLEDAI score, the transcriptional score increases by 1.3. Overall, SLEDAI index scores and transcriptional scores reflected similar activities

according to their respective scales in all but six patients (SLE31, SLE78, SLE125, SLE130, SLE135, and SLE99), in whom the transcriptional U scores were disproportionately high as compared to SLEDAI index scores (SLEDAI values are positive, whereas multivariate U scores can be positive or negative). One of the patients, with the highest discrepancy (SLE78), was diagnosed during the follow-up period with a life-threatening complication (pulmonary hypertension), which is not computed within the SLEDAI. Thus, severity of disease was more accurately assessed by the transcriptional score. Disease flaring and subsequent recovery was detected in one patient (SLE31) during longitudinal follow up with the use of both SLEDAI scores and transcriptional score. Interestingly, however, not only does the amplitude of change observed in the case of the transcriptional U score appear to be much greater (0 to 40 versus 6 to 10 for SLEDAI), but an increase could already be detected at the second time point, two months before the worsening of this patient's clinical condition was detected by SLEDAI. Thus, these data illustrate the potential value of microarray data and the multivariate transcriptional scores derived from it for the longitudinal follow up of disease progression in patients with complex multisystemic diseases like SLE.

Composite Transcriptional Vectors Are Stable across Laboratories and Microarray Platforms

To be truly viable as biomarkers, composite transcriptional vectors must prove reliable. Early on, poor reproducibility of microarray results obtained by different laboratories and across platforms raised suspicion about the validity of these results, and this remains a major concern (Bammiller et al., 2005; Frantz, 2005; Ioannidis, 2005; Irizarry et al., 2005; Larkin et al., 2005; Michiels et al., 2005; Shi et al., 2006). We compared transcriptional profiles obtained with the use of two commercial microarray platforms, Affymetrix and Illumina. PBMCs were isolated from four healthy volunteers and ten liver-transplant recipients. Starting from the same source of total RNA, we independently generated targets and analyzed them with Affymetrix U133 GeneChips (at the Baylor Institute for Immunology Research) and Illumina Human Ref8 BeadChips (at Illumina). Fundamental differences exist between the two microarray technologies (see Experimental Procedures for details). Probe IDs provided by each manufacturer were converted into a common ID that was used for matching gene-expression profiles. Overall, the Affymetrix and Illumina profiles for M3.1 appear to be similar (Figure 6). However, correlations comparing both platforms performed for individual genes forming M3.1 resulted in a median R^2 value of 0.36 (ranging from 0.17 to 0.55). In other modules, such as M1.2 and M3.2, correlations observed at the level of individual genes were also poor (R^2 median [range] = 0.13 [0.02–0.5] for genes forming M1.2 and 0.19 [0.06–0.4] for genes forming M3.2; Figure 6). In order to compare the overall modular expression pattern across the two platforms, we derived for each module a composite transcriptional vector (averaging the values obtained for the genes forming each module). Remarkably, the module-level expression values thus derived from Affymetrix and Illumina data were highly comparable (Figure 6; transplant group Pearson correlation coefficient $R^2 = 0.83$, 0.98, and 0.93, for M1.2, M3.1, and M3.2 respectively; $p < 0.0001$ —in addition, R^2 values of M1.1 = 0.84, M1.3 = 0.95, M1.4 = 0.81, M1.5 = 0.74,

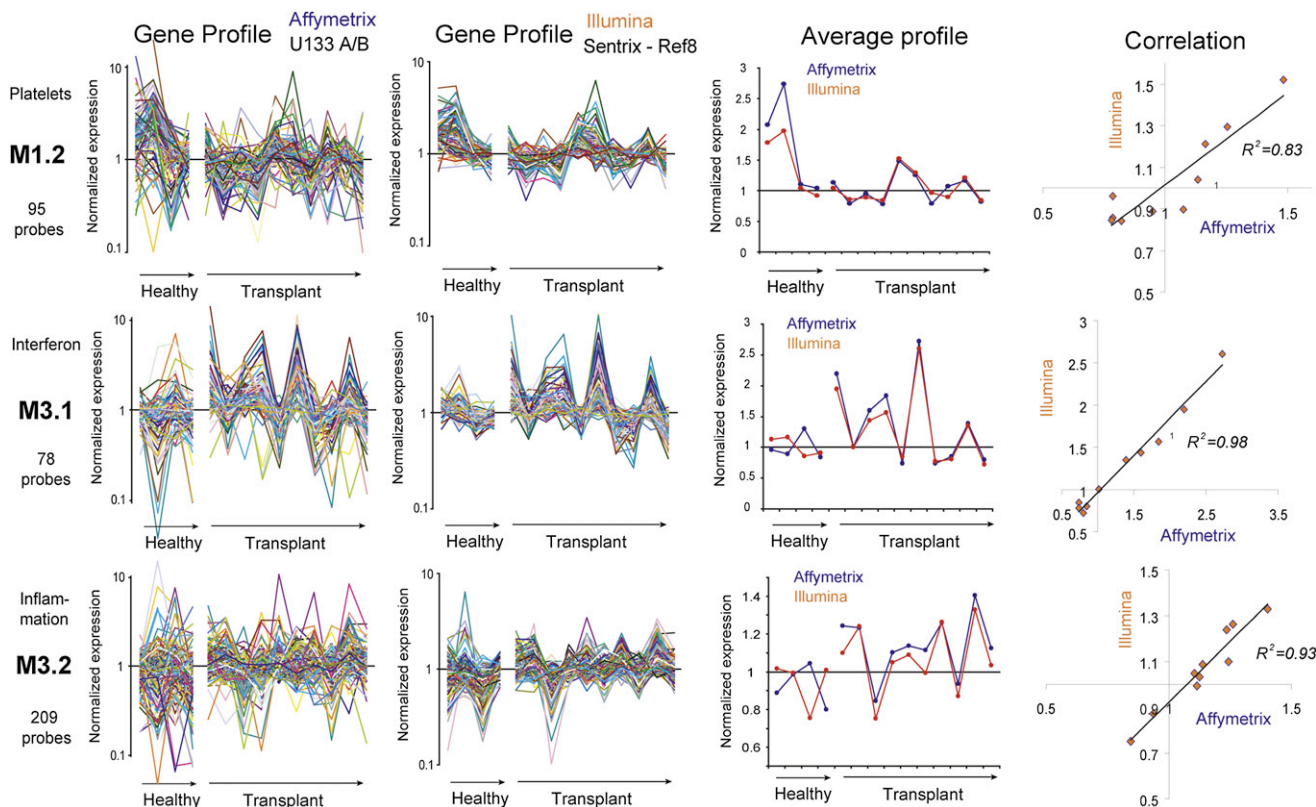

Figure 6. Cross-Microarray Platform Comparison

PBMC samples from healthy donors and liver-transplant recipients analyzed on two different microarray platforms: Affymetrix U133A&B GeneChips and Illumina Sentrix Human Ref8 BeadChips. The same source of total RNA was used to independently prepare biotin-labeled cRNA targets. Expression is normalized to the median of measurements obtained across all samples. Averaged expression values of the genes in each module are shown for both Affymetrix and Illumina platforms.

M1.8 = 0.62, M2.1 = 0.98, M2.2 = 0.82, M2.3 = 0.99, M2.6 = 0.73, M2.8 = 0.83, M2.10 = 0.66, M3.3 = 0.65, M3.8 = 0.57; R^2 values for other modules < 0.5). Taken together, these results indicate that module-level composite expression data produce a more stable metric than do individual gene-expression values, thereby enhancing data reproducibility across microarray platforms. This property may be attributed to the stringent module-selection process (transcripts must be coexpressed across many samples) and to the fact that composite expression values are derived from multiple measurements (smoothing the imprecision observed at the level of individual probes).

DISCUSSION

Patient blood transcriptional profiling studies generate large-scale data that are difficult to exploit. Adopting a module-based data-mining strategy can facilitate biomarker and biological knowledge discovery by focusing the analysis of microarray data on stable sets of transcripts selected on the basis of their clustering pattern across diseases.

The module-construction strategy that we have designed takes advantage of the biological variability inherent to patient-based studies in order to identify the major transcriptional components of this system. A clustering algorithm teases apart the patterns emerging from the blood profiles obtained for different diseases. Once patterns have been identified for each disease, the cluster membership of individual transcripts is compared. A module is formed of transcripts found to always belong to the same clusters across all diseases (eight out of eight in our example). The stringency of this requirement is progressively relaxed during the subsequent rounds of selection so that modules are formed when transcripts fall in the same clusters in any combination of seven diseases (round 2) or of six diseases (round 3). This stepwise reduction of the stringency of filtering criteria accounts for the fact that transcripts may not be “turned on” in all diseases. Indeed, modules linked to interferon or to inflammation (M3.1 and M3.2) were, for instance, not formed until the third round of selection. The validity of the transcriptional modules thus generated was verified by different approaches. Random permutations attested to the statistical validity of the module construction, and coexpression was confirmed in independent

Figure 5. Longitudinal Disease Monitoring with a Multivariate Disease-Activity Score

SLEDAI index (blue, right y axis) and transcriptional U scores (red, left y axis) of pediatric patients (identified by an SLE ID) over time (x axis). Time elapsed between sampling is indicated in months.

data sets (PBMC samples from healthy volunteers or from patients with *S. pneumoniae* infection who were not used to identify modules) across laboratories and microarray platforms (Affymetrix versus Illumina). Furthermore, as should be expected of transcriptional modules, literature profiling of genes forming each of the modules revealed significant functional convergence, with half of the modules associated with clearly identifiable functional themes.

With the inclusion of profiles from a wide range of diseases, our goal was to identify a “universal” set of modules that could be used as a stable framework for subsequent analysis of any PBMC data set. However, we anticipate that adding more diseases to the selection pool will result in a refined partitioning of the modules already identified and will add modules to the existing set. Also, although the collection of genome-wide PBMC transcriptional profiles used for module selection is already extensive, the identification of a definitive module set will require expanding the scale of this analysis.

Reducing the dimension of microarray data makes it more amenable to interpretation. When confronted with such an overwhelming amount of information, it is necessary to reduce it to a manageable number of variables and to use visualization schemes as a means to facilitate the identification of patterns in the data, especially when performing comparisons across diseases. Furthermore, after functional interpretation, we found that the modules identified are linked to the two components driving differential gene expression in blood: changes in relative cellular abundance (e.g., B cell, cytotoxic cell modules) and in gene regulation (e.g., inflammation, interferon). Thus, overlaying these functional annotations to the fixed module patterns further supports the interpretation of disease fingerprints. Inevitably, however, reducing microarray data to a small set of variables and broad functional categories can only offer an oversimplified view of the data, and interactive mining tools are therefore necessary to restore the unique depth perspective that systems-scale data are able to provide.

We have also explored the use of transcriptional modules as a basis for biomarker discovery. By construction, modules include only transcripts which coclustered in at least six out of eight diseases across many samples. The probability of this happening just by chance is very low. In fact, when we ran tests in which gene labels were permuted randomly in the different diseases, we could not identify any modules. Also, the use of sets of transcriptional modules as a basis for biomarker discovery should help researchers focus on biologically relevant transcripts. Another potential benefit of using modules as a framework for biomarker discovery is that it allows the reduction of the dimension of microarray data. Identifying a small set of clinically valuable markers from tens of thousands of candidates in a single analysis step is a considerable challenge; noise is, again, a major issue. However, when the data are reduced from over 44,000 variables to about 5000 distributed in 28 modules, biomarker discovery becomes a much more manageable proposition. In the case of SLE, comparisons carried out on a module-by-module basis identified 11 submodules with a minimum of 15% of transcripts overexpressed or underexpressed as compared to those of healthy volunteers. Once the data are reduced to 11 composite values (or transcriptional vectors), it then becomes possible to summarize the results as one single multivariate score. Repeating mea-

surements for multiple transcripts sharing the same pattern within a module also makes for a more robust measurement, which explains, at least in part, the level of correlation measured between data generated on two microarray platforms in two independent laboratories. Finally, the fact that some of the modules can be associated to well-recognized biological pathways linked to disease pathogenesis will help in further asserting the credibility of biomarkers derived from such analysis.

Indeed, upon being identified, SLE vectors were validated in an independent set of samples. Furthermore, multivariate-resulting transcriptional scores were correlated to clinical disease-activity indices in both cross-sectional and longitudinal sets of samples. Our data demonstrate that composite transcriptional vectors can be directly correlated to clinical disease activity in patients with lupus.

In conclusion, the modular-analysis framework that we have generated could prove useful for the discovery of diagnostic or prognostic markers and provide the means for monitoring disease progression and response to treatment in other complex-disease settings.

EXPERIMENTAL PROCEDURES

Patient Information

Subjects were recruited at the Baylor University Medical Center of Dallas, the Texas Scottish Rite Hospital, and the Children's Medical Center of Dallas. The study was approved by the Institutional Review Boards of UT Southwestern Medical Center, Texas Scottish Rite Hospital, and Baylor Health Care System, and informed consent was obtained from all patients (legal representatives and patients over 10 yr of age). Bacterial and viral infections were confirmed by standard bacterial cultures, direct fluorescent antigen testing, and viral cultures. Patients with infections were recruited once a confirmed microbiologic diagnosis was established. The clinical and demographic characteristics of SLE patients are summarized in [Table S4](#).

Processing of Blood Samples

Blood samples were collected in acid citrate dextrose or EDTA tubes (BD Vacutainer) and immediately delivered at room temperature to the Baylor Institute for Immunology Research, Dallas, TX, for processing. PBMCs were isolated via Ficoll gradient and immediately lysed in RLT reagent (QIAGEN, Valencia, CA) with beta-mercaptoethanol (BME) and stored at -80°C prior to the RNA-extraction step.

Microarray Analysis

Total RNA was isolated with the RNeasy kit (QIAGEN) according to the manufacturer's instructions, and RNA integrity was assessed with an Agilent 2100 Bioanalyzer (Agilent, Palo Alto, CA).

Affymetrix GeneChips

Target labeling was performed according to the manufacturer's standard protocol (Affymetrix, Santa Clara, CA). Biotinylated cRNA targets were purified and subsequently hybridized to Affymetrix HG-U133A and U133B GeneChips ($> 44,000$ probe sets). Arrays were scanned with an Affymetrix confocal laser scanner. Microarray Suite, Version 5.0 (MAS 5.0; Affymetrix) software was used to assess fluorescent hybridization signals, to normalize signals, and to evaluate signal-detection calls. Normalization of signal values per chip was achieved with the MAS 5.0 global method of scaling to the target intensity value of 500 per GeneChip. A gene-expression analysis software program, GeneSpring, Version 7.1 (Agilent), was used to perform statistical analysis and clustering.

Illumina BeadChips

Samples were processed and data were acquired by Illumina (San Diego, CA). Targets were prepared with the Illumina RNA amplification kit (Ambion, Austin, TX). cRNA targets were hybridized to Sentrix HumanRef8 BeadChips ($> 25,000$ probes), which were scanned on an Illumina BeadStation 500. Illumina's

Beadstudio software was used for assessment of fluorescent hybridization signals.

Quantitative Real-Time PCR

Biotinylated cRNA prepared for microarray analysis was reverse transcribed into cDNA with the High-Capacity cDNA Reverse Transcription Kits (Applied Biosystems, Foster City, CA). Real-time PCR was set up with Roche Probes Master reagents and Universal Probe Library hydrolysis probes. PCR reaction was performed on the LightCycler 480 (Roche Applied Science). Secondary derivative calculation data were collected, and cross point values of target genes were normalized to two housekeeping genes (*ARHGDI*B and *GUSB*).

Module-Construction Algorithm

Our goal was to extract from an extensive leukocyte microarray data set groups of coordinately expressed transcripts spanning multiple diseases (i.e., identifying genes in which expression is correlated across multiple samples). Although the initial steps of our approach produce clusters of coordinately transcribed genes in a manner similar to other groups, we refine the process by generating modules based on cluster membership across multiple independent microarray experiments: (1) Parallel analyses were performed, grouping transcripts for eight different disease data sets with the K-means clustering algorithm. (2) Transcripts that are coexpressed in the context of several diseases were then identified (i.e., we examined cluster membership across multiple independent microarray experiments). Also, in the first round of selection, we started by choosing transcripts with shared cluster membership for all eight diseases. For the subsequent round of selection, we accounted for the fact that the different diseases might produce different patterns; thus, we decreased the level of stringency accordingly (i.e., allowing for one or even two diseases to be dropped in the second and the third rounds of selection, respectively). In summary, this approach relies on the K-means clustering algorithm and is tailored to capture transcriptional modules spanning multiple diseases, starting with a large number of transcripts. This module-construction algorithm is described in detail in the [Supplementary Experimental Procedures](#).

Multivariate U Scores

The detailed explanation of this method has been published recently (Wittkowski et al., 2004), and the required tools are available at <http://Mustat.Rockefeller.edu>. In brief, scores were obtained by computation of the average normalized expression levels for all transcripts within the modules that were identified as differentially expressed in SLE PBMCs.

Literature Profiling

The literature profiling algorithm employed in this study has been previously described in detail (Chaussabel and Sher, 2002). This approach links genes sharing similar keywords. It uses hierarchical clustering to analyze patterns of term occurrence in literature abstracts.

Association between SLEDAI Scores and Multivariate U Scores

Linear regression was used in the cross-sectional analyses for assessment of the association between the multivariate “transcriptional scores” and SLEDAI scores for the treated and untreated pediatric SLE patients. Results and figures were obtained with JMP statistical software (Version 7; SAS Institute). When this association was assessed for the corresponding longitudinal data, a linear mixed-effect model with a random intercept was used to account for the repeated and unequally spaced observations. This modeling technique is well described in such texts as Verbeke and Molenberghs (Verbeke and Molenberghs, 2000) and Fitzmaurice et al. (Fitzmaurice et al., 2004). SAS statistical software (Version 9.1; SAS Institute) was used for this portion of the analysis.

ACCESSION NUMBERS

The microarray data used in this study have been deposited in NCBI's Gene Expression Omnibus (GEO) with the accession number GSE11907.

SUPPLEMENTAL DATA

Supplemental data include supplemental experimental procedures, five figures, and five tables and can be found online at <http://www.immunity.com/cgi/content/full/29/1/150/DC1/>.

ACKNOWLEDGMENTS
